Date:

## Preface

This thesis is conducted as a part of the Master of Science in Logistics at Molde University College, Specialized University in Logistics. This paper marks the end of our studies in Operations Management.

This research was conducted between November 2015 and May 2016.

We will like to thank our supervisor Professor Johan Oppen at Møreforskning Molde AS for helpful advice and insightful comments during our work with this thesis.

This thesis concerns the topic of routing of aircraft in northern Norway.

Marthe Vaseng Arntsen and Lisa Skavnes
Molde, Norway
May 2016

#### Abstract

This thesis concerns the topic of routing of aircraft in northern Norway. The purpose of the thesis was to make a relatively small model that could optimize the routes, when minimizing the total distance travelled.

The focus of the thesis was on the regional flight routes in the northern part of Norway. This is a special area when it comes to air transportation, there are long distances, few people, many small airports and chained trips with two or more legs. The regional air transport is regulated by PSO, which means that some legs have to be traversed even though it is not profitable. The focus of the thesis was on 28 airports in northern Norway and Trøndelag.

Due to the size of the problem, we decided to use a two-phase approach. The first step was to use the Fisher and Jaikumar algorithm and a model for the General Assignment Problem to divide the airports into clusters. Each cluster was built around a depot.

The second step was to make routes for each cluster using our modified model for a Vehicle Routing Problem. The model we made, takes into account the number of landings at each airport, the maximum duration of a roundtrip, the number of landings per roundtrip and the arrival and departure time at the depot and airports.

We have tested our model using six different scenarios. The scenarios contain different number of depots and different depots. The different depots were chosen based on the geographical location and the size of the airports. We compared the different scenarios based on the total distance travelled, the total cost and the total travel time.

The scenario that gave us the best solution, have Trondheim, Bod $\varnothing$, Troms $\varnothing$ and Kirkenes as depots. The depots are evenly spread among the area, and are located in different regions. The two-phase approach gave a reasonable solution, but in order to use the model on real life instances more extensions need to be implemented.

## Table of Contents

1.0 Introduction ..... 1
2.0 Problem description ..... 2
2.1 The geography and the airports in the north of Norway ..... 2
2.2 PSO - Public service regulations ..... 4
2.2.1 PSO routes in northern Norway .....  5
2.3 Laws and regulations concerning air traffic ..... 6
2.4 What we want to achieve with our research ..... 7
2.5 Research questions ..... 7
2.5.1 Main research questions ..... 7
2.5.2 Sub-questions ..... 7
3.0 Literature review ..... 8
3.1 VRP ..... 8
3.1.1 TSP ..... 9
3.1.2 The basic VRP ..... 9
3.1.3 VRP Extensions ..... 11
3.2 Exact solution methods ..... 13
3.2.1 Branch-and-Bound ..... 13
3.2.2 Cutting plane ..... 13
3.2.3 Branch-and-cut ..... 14
3.3 Heuristics ..... 14
3.3.1 Classical heuristics ..... 14
3.3.2 Metaheuristics ..... 16
3.4 Aircraft routing ..... 17
3.5 Other relevant articles ..... 18
4.0 Analysis. ..... 19
4.1 Modeling choices and assumptions ..... 19
4.1.1 Uncertainty ..... 19

### 1.0 Introduction

Norway has an unwelcoming nature with mountains, rivers, fjords, glaciers and moors, this combined with a rough climate make parts of the country less reachable. The topography results in large distances between settlements. The key factor to connect these remote areas to the rest of the world is to have a good air transportation network. Without good air transportation, these large areas would be more or less isolated. Air transport services are very important and it allows natural and human resources to be used efficiently in the society (Williams and Bråthen 2010).

Air transportation is very important when looking at the beneficial outcome in the society. "The benefit of high-speed travel mode like air transportation may be reflected in many ways: industries are better off, income levels are higher, population development is more favorable and the feeling of being remote is lower than if there are no air service." (Williams and Bråthen 2010, p. 61).

To ensure coverage of remote airports, the European Union established Public Service Obligations (PSO). The purpose of the PSO regulations is to ensure a minimum level of air service to the areas that depend on air transportation when considering the economic development of the regions.

Northern Norway has a special air transportation network, where many of the routes are chained air trips with two or more legs and most of the airports are small. These types of airports are called short take-off and landing (STOL) airports and they have a runway that is about 800 meters long. The focus in this thesis will be on 28 airports located in northern Norway and in Trøndelag.

Our supervisor Johan Oppen introduced us to this topic. It was brought to his attention when Møreforsking was writing a report for the Norwegian Ministry of Transportation and Communications. The topic of the report was the tendering arrangements for regional flights in northern Norway (Bråthen et al. 2015).

Routing of aircraft is an area that is not much explored when considering the model building part. Different models have been made, most of these are large and complex, which makes them difficult to solve.

### 2.0 Problem description

Today, there is one big actor operating in the aviation market in northern Norway. This actor is Widerøe, they have been operating routes in this area since 1955. Widerøe was one of the actors that were fighting a political battle to make the authorities open a STOL network in Norway. During the1960s and 1970s the authorities finally decided to establish small regional airports. The building of the regional airports on Helgeland was the first step in building a STOL network in Norway (Widerøe 2016). The already existing routes will not be analyzed in this thesis. Instead, we will explore if it is possible to make a mathematical model that can find the most efficient routes, considering different factors and objectives.

### 2.1 The geography and the airports in the north of Norway

As mentioned before, Norway is an elongated country with large distances between populations, mainly because of obstacles like mountains, rivers, moors and fjords. In the north there are additional factors that can affect the living conditions, one of these factors could for example be the extreme winter season with cold weather and few hours of daylight. These factors can also affect the transportations network in terms of closed roads, and railways, and bad landing conditions for aircraft.

There are different transportation methods that can be used when travelling in northern Norway. The options are to go by air, road, railway or sea. The last option might not be that favorable since it is both very time consuming and weather dependent. To go by road might be a good option if the distances are short. The Norwegian railway system does not go further north than Bod $\varnothing$, so this is often not an alternative. Ofotbanen goes between Narvik and the Swedish border, this will not be included as an alternative since it is not connected to the rest of the Norwegian railway system. Travelling by air seems to be the best option, since it is possible to travel large distances in relatively short time.

Only about $11 \%$ of the total population in Norway lives in northern part. Still, more than $50 \%$ of Avinors airports are located in this region (Store Norske Leksikon 2009).

Figure 1: Map of all Avinors airports

Figure 1 presents all Avinors airports in Norway (Avinor 2016a). In this thesis, the focus will be on the airports in northern Norway as well as the airports Trondheim, Rørvik and Namsos. Based on the length of the runway, the airports can be divided into three different categories, those are small airports - where the runway is less than 1000 meters, mediumsized airports - 1000 to 1799 meters and large airports - longer than 1799 meters. In table 1 , we present the airports and their runway lengths.

| Small airports | Medium airports |  |  |
| :--- | :--- | :--- | :--- |
| Vard $\varnothing$ | 905 | Kirkenes | 1605 |
| Vads $\varnothing$ | 830 | Sandnessjøen | 1199 |
| Mehamn | 830 | Brønnøysund | 1199 |
| Leknes | 830 |  |  |
| Rørvik | 830 | Large airports |  |
| Berlevåg | 829 | Bod $\varnothing$ | 2794 |
| Mosjøen | 829 | Evenes | 2716 |
| Hammerfest | 824 | Lakselv | 2604 |
| Båtsfjord | 810 | Andenes | 2468 |
| Moi Rana | 801 | Trondheim | 2446 |
| Honningsvåg | 800 | Troms $\varnothing$ | 2003 |
| Narvik | 800 | Bardufoss | 1970 |
| Hasvik | 799 | Alta | 1907 |
| Storslett/Sørkjosen | 799 |  |  |
| Stokmarknes | 799 |  |  |
| Namsos | 798 |  |  |
| Svolvær | 776 |  |  |

## Table 1: Airports and their runway lengths

(Avinor 2016a)

### 2.2 PSO - Public service regulations

In order to enable governments to maintain essential air services, Article 16, 17 and 18 of Regulation (EEC) No. 1008/2008 define a system of public service obligations (PSOs) which can impose on carriers operating on designated routes. In essence, the legislation allows Member States to impose a public service obligations in respect of scheduling air service between any airport in the Community and an airport serving a peripheral or development region within its territory or on a thin route to any airport in its territory considered vital for the economic and social development of the region served by the airport. If no airline is willing to provide a service under the conditions imposed, the government may restrict access to the route to a single carrier and award financial compensation to the carrier in return for compliance with the PSO. (Williams 2010,p. 99)

Looking at the list of Public Service Obligations provided by the European Commission in December 2015, Norway is the country with the largest number of PSO routes (51), followed by France (45) (European Commission 2015). One of the reasons why Norway has so many PSO routes is because of the large distances and the relatively small number of people living in the districts. The small number of people living there results in low revenue for the airlines and makes the routes unprofitable in the free market. The Norwegian Ministry of Transport and Communications carries out the PSO tendering
process. Before the PSO tendering process is carried out, the Ministry sends out an "Invitation to tender". This document consists of obligations applied to the individual routes, which says something about the minimum frequencies, seating capacity, routing and the timetables.

### 2.2.1 PSO routes in northern Norway

The Ministry tenders the PSO routes out for a period of about 4 years each time. The PSO routes in northern Norway were last out for tendering in 2012, and this agreement lasts until 2017. Below we see an overview over the routes that were included in the PSO tendering process in 2012 (Northern Norway) and 2013 (Finmark and North-Troms).

## Northern Norway:

1. Lakselv - Tromsø v.v.
2. Andenes - Bodø v.v.
3. Svolvær - Bodø v.v.
4. Leknes - Bodø v.v.
5. Narvik (Framnes) - Bodø v.v.
6. Brønnøysund - Bodø v.v., Brønnøysund - Trondheim v.v.
7. Sandnessjøen - Bodø v.v., Sandnessjøen - Trondheim v.v.
8. Mo i Rana - Bodø v.v., Mo i Rana - Trondheim v.v.
9. Namsos - Trondheim v.v., Rørvik - Trondheim v.v.
(The Ministry of Transport and Communications 2012a)

## Finnmark and North-Troms:

1. Routes between Kirkenes, Vads $\varnothing$, Vardø, Båtsfjord, Berlevåg, Mehamn, Honningsvåg, Hammerfest and Alta.
2. Hasvik - Tromsø v.v., Hasvik - Hammerfest v.v., Sørkjosen - Tromsø v.v." (The Ministry of Transport and Communications 2012b)

Examples of obligations applying to the route Lakselv - Tromsø:

|  | Weekdays (Mon-Fri) | Weekends (Sat-Sun) |
| :--- | :--- | :--- |
| Frequencies | Min. 3 daily return services | Min. 3 return services combined |
| Seating <br> capacity | 690 seats in both direction | 135 seats in both directions |
| Routing | In both directions at least 2 of the required daily <br> services should be non-stop | In both directions, at least 2 of <br> the required services combined <br> shall be non-stop. |
| Timetables | First arrival Tromsø no later than 08.30. <br> Last departure from Tromsø no earlier than 19.30. <br> First departure from Tromsø should be no later <br> than 11.30. <br> Last departure from Lakselv no earlier than 17.00 |  |
| Aircraft | Minimum 30 seats |  |

Table 2: PSO applying to the route Lakselv - Troms $\emptyset$

These obligations apply throughout the year. There are different requirements for each route included in the tendering process.

### 2.3 Laws and regulations concerning air traffic

When conducting a flight plan, many law and regulations should be followed. Presented below are the regulation we consider most important for our problem:

- Home base - Each aircraft needs to have a permanent home.
- Flight duty period (FDP) - this is the time during which a person operates in the aircraft as a member of its crew. For a flight that starts between 17.00 and 05.00 the maximum flight duty period is 10 hours, for short-haul flights starting between 06.00 and 13.29 the maximum duration is 13 hours. In some cases the FDP can be maximum 14 hours, this is only if the flights starts between 07.00 and 13.29 and the resting period before and after the flight is extended (EASA European Aviation Safety Agency 2016b). Between 13.30 and 16.59 the maximum duration decreases 15 minutes for each half hour, starting at 12 hours and 45 minutes at 13.30 and ending at 11 hours and 15 minutes at 16.59 (EASA European Aviation Safety Agency 2016a).

There are also regulations regarding maintenance on the aircraft. There are two types of maintenance:

- Ongoing maintenance, a regular inspection and correction of minor errors.
- Heavier maintenance that occurs in regular intervals, this could be based on number of landings, flight time or a specific number of weeks, months, etc..

### 2.4 What we want to achieve with our research

During our research, we want to make a model that will give us a reasonable and feasible solution. The goal is to make the model such as it takes into account all the deterministic factors, like the PSO regulations and the laws and regulations concerning air traffic. We will use different objectives like minimizing total distance, total cost and total travel time when testing our model. In addition, will we analyze the different routes given by the different objectives and try to combine the solutions into one optimal route.

### 2.5 Research questions

The questions we want to answer throughout the work on this thesis will be presented in this section.

### 2.5.1 Main research questions

1: Is it possible to make a model that is solvable in reasonable time and also gives a feasible solution?

2: What is the best combination of routes?

### 2.5.2 Sub-questions

1.1: What research has been done in this area?
1.2: Is the solution possible to implement in real life?
1.3: What happens to the computation time when we add one more airport?
1.4: How many variables and constraints can the model contain, and still be solvable?
1.5: Can we combine different existing models to make one that fits our problem?
2.1: Which combination of clusters gives the best solution?
2.2: Are the PSO regulations and the laws considered in these routes?

### 3.0 Literature review

The relevant theory and literature for our thesis will be presented in this chapter. This includes the Vehicle Routing Problem, exact solution methods, heuristics and previously work in the field of VRP and aircraft routing. The VRP is a well-covered topic, the more specific problem of aircraft routing is less researched.

### 3.1 VRP

The Vehicle Routing Problem (VRP) is a combinatorial optimization and integer programming problem that seeks to service a number of customers with a fleet of vehicles. The main goal of the VRP is to find a set of routes at a minimum cost (time, travel distance, number of trucks, etc.), beginning and ending in the same node, and at the same time fulfilling the demands of all the nodes. The vehicles have a limited capacity and each node can only be visited once. Laporte defined VRP as the problem of "designing leastcost delivery routes from a depot to a set of geographically scattered customers, subject to side constraints" (Laporte 2009, p. 408).

Dantzig and Ramser first introduced the VRP in the article "The Truck Dispatching Problem" from 1959. In the paper, they dealt with the problem of finding the optimum routes for a fleet of gasoline delivery trucks, between a depot and a number of stations. They tried to find a method for assigning stations to trucks, such that the demand is fulfilled and the total distance travelled is minimized. In this article they formulated the problem as a generalization of the "Travelling-Salesman Problem" (Dantzig and Ramser 1959).

Figure 2 shows an example of a typical input for a VRP. In this example there are 16 customers represented by the blue points and one depot in the middle. Figure 3 shows one of the possible solutions for the instance in figure 2 .

Figure 2:An instance of a VRP

Figure 3: Feasible solution of a VRP instance

### 3.1.1 TSP

The "Travelling Salesman Problem" is defined as the problem of "finding a route of a salesman who starts from a home location, visits a prescribed set of cities and returns to the original location in such a way that the total distance travelled is minimum and each city is visited exactly once" (Gutin and Punnen 2007, p. 1). The TSP is a hard combinatorial optimization problem, but an optimal solution can be found for problems with up to several thousand of nodes. The VRP is a much harder problem.

The TSP can be visualized using a complete graph $G$, which can be directed or undirected. Each edge has a cost associated with it. The objective of the TSP is to find a tour (Hamiltonian cycle) in $G$, such that the cost is minimized (the sum of costs of all edges in the tour). A Hamiltonian cycle is a route that visits each node exactly once (Gutin and Punnen 2007).

### 3.1.2 The basic VRP

The basic version of the VRP is the capacitated VRP (CVRP). Here, all the customers correspond to deliveries. The demand from the customers is deterministic, which means that it is known in advance. In addition, the demand cannot be split. There is a set of identical vehicles with a given capacity, and one depot from where the vehicles depart and arrive. The objective of the CVRP is to minimize the total cost, while serving all the customers (Toth and Vigo 2002).

The CVRP is defined on a complete graph $G=(V, A)$ where $V=\{0, . . n\}$ is a set of nodes and $A$ is the arc set. The vertices $i=1, . ., n$ correspond to the customers. Node 0 represents the depot. The node $(n+1)$ can also represent the depot. There is a travel $\operatorname{cost}, c_{i j}$, associated with each arc $(i, j) \in A$, which is the cost of travelling from node $i$ to node $j$. It is not allowed to use loop arcs, (i,i) (Toth and Vigo 2002).

The CVRP can be asymmetric or symmetric. When the cost matrix is asymmetric, it means that the cost of travelling between two nodes $i$ and $j$ is different based on which direction you travel. This problem is called the asymmetric CVRP (ACVRP). In the symmetric version (SCVRP), the cost matrix is symmetric $c_{i j}=c_{j i}$ for all $(i, j) \in A$ (Toth and Vigo 2002).

The customers have a nonnegative demand, $d_{i}$, that should be delivered. The depot does not have a demand. At the depot, a set of $K$ vehicles are available to serve the customers. Each vehicle has a given capacity $C$. To ensure that the problem is feasible, the demand from any customer should be less than the vehicle's capacity. A vehicle can only drive one route. The minimum number of vehicles needed to serve the customer set S is denoted by r(S) (Toth and Vigo 2002).

The CVRP aims to find a set of exactly $K$ routes with a minimum cost (sum of the costs of all arcs included in the route). These routes have to satisfy the constraints such that each route visits the depot, each customer are visited by exactly one route and the sum of the demand from the customers visited on a route does not exceed the vehicle's capacity (Toth and Vigo 2002).

Next, the basic model for the VRP will be presented.

## Objective function

$$
\begin{equation*}
\min \sum_{i \in V} \sum_{j \in V} c_{i j} * X_{i j} \tag{1}
\end{equation*}
$$

Subject to

$$
\begin{equation*}
\sum_{i \in V} X_{i j}=1 \quad \forall j \in V \backslash\{0\} \tag{2}
\end{equation*}
$$

$$
\begin{array}{ll}
\sum_{j \in V} X_{i j}=1 & \forall i \in V \backslash\{0\} \\
\sum_{i \in V} X_{i 0}=K & \\
\sum_{j \in V} X_{0 j}=K & \\
\sum_{i \notin S} \sum_{j \in S} X_{i j} \geq r(S) & \forall S \subseteq V \backslash\{0\}, S \neq \emptyset \\
X_{i j} \in\{0,1\} & \forall(i, j) \in V
\end{array}
$$

This model is a two-index vehicle flow formulation; the binary variable X is used to indicate which arcs that are travelled in the optimal solution. The objective of the model is to minimize total cost of the routes. Constraint (2) says that exactly one arc has to enter each node $j$, and constraint (3) ensures that exactly one arc has to leave each node $i$. Constraints (4) ensures that the number of arcs into the depot is equal to the number of vehicles, and constraint (5) ensures that the number of arcs out from the depot should be equal to the number of vehicles. Constraint (6) is a capacity cut constraint that imposes both the vehicle capacity requirement and the connectivity of the solution. The variables domain are given in constraint (7) (Toth and Vigo 2002. P. 12).

### 3.1.3 VRP Extensions

There exist several variants of the VRP. One extension is where the number of available vehicles is higher than the minimum number of vehicles needed. In this case, it is normal that each vehicle has a cost associated with using it and a new constraint will be to minimize the number of routes driven. Another version will be when the vehicles have different capacities (Toth and Vigo 2002).

Figure 4: Shows the VRP extensions mentioned in this thesis

The version Distance-Constrained VRP (DVRP) is when the capacity constraint is replaced by a maximum length or time constraint. Each arc is associated with a nonnegative length. The total length of a route cannot exceed the maximum length of a trip. When the length of an arc is given in travel time, a service time at each customer may be given (number of time periods the vehicle must stop at the customer). The objective is to minimize the total length or duration of the routes, when service time is included (Toth and Vigo 2002).

In the VRP with Time Windows (VRPTW) each customer has a time window, which decides when the service at the customer should start and end. The travel time for each arc and the service time at each customer is also given. If the vehicle arrives at the customer before the time window opens, it must wait before starting the service. The VRPTW aims to find a set of routes that minimizes the total costs, and satisfy the constraints such that each route visits the depot, each customer is visited by exactly one route, the demand on the route does not exceed the vehicle's capacity and each customer is served within their time window (Toth and Vigo 2002).

The VRP with Backhauls (VRPB) is an extension of the CVRP. Here, the customers are divided into two subsets, linehaul and backhaul customers. With linehaul customers the delivery demand is higher than the pickup demand, for backhaul customers it is opposite. In VRPB, there is a precedence constraint between the customers; all linehaul customers have to be served before backhaul customers on a route. In the VRPB, the aim is to find a set of routes, with a minimum cost, that will satisfy a number of constraints. Each route visits the depot, each customer is visited by one route, the total demand of the
customers on the route does not exceed the capacity of the vehicle and in each route, the linehaul customers are served before the backhaul customers. Routes that contain only backhaul customers are not allowed. (Toth and Vigo 2002).

In VRP with Pickup and Delivery (VRPPD), each customer has both a pickup and delivery demand ( d and p ). The demand can sometimes be presented with only one quantity, the net demand (positive or negative). In the VRPPD, it is assumed that delivery is performed before the pickup. The load before arriving at a customer is calculated as the starting load from the depot minus all delivered demand plus all that is picked up from the customers already visited. The aim of the VRPPD is to find a set of routes, that minimizes the total cost and satisfies the constraints. Each route has to visit the depot, each customer is visited by only one route and the load along the route can neither be negative nor exceed the capacity of the vehicle (Toth and Vigo 2002).

In VRP with multiple depots, there are multiple depots where the vehicles can be scheduled to leave from.

### 3.2 Exact solution methods

The next chapter is going to present the exact methods that can be used to solve our problem. Exact methods in general are not able to find the optimal solution in reasonable time for problems with more than 50 customers (Oppen and Løkketangen 2006). The disadvantages of using an exact method is that it usually have long computation time, on the other hand these methods always give a globally optimal solution. The most used exact methods are branch-and-bound and the branch-and-cut algorithms.

### 3.2.1 Branch-and-Bound

The Branch-and-Bound algorithm is defined in (Winston 2003) as a method which implicitly enumerates all possible solutions to an integer problem. By solving a sub problem, many possible solutions may be eliminated from consideration. Branch-andbound is also well described in (Laporte 2009).

### 3.2.2 Cutting plane

The Cutting plane method starts with finding a solution to a linear problem. If the solution to the problem is fractional, it can be solved by creating a set of constraints that can cut off
the fractional solution. The new solution is optimal if it is integer. If the solution is not integer, then continue to add new constraints until an integer solution is found (Toth and Vigo 2002).

### 3.2.3 Branch-and-cut

The Branch-and-Cut algorithm is presented in (Mitchell 2002) as a method that guarantees optimality. The algorithm is a combination of a cutting plane method and a branch-andbound algorithm. The algorithm consists of solving the linear relaxation to get an integral solution, and then proceeds with a classical branch-and-bound method (Toth and Vigo 2002).

### 3.3 Heuristics

A heuristic is a method for solving a problem. This method can give a good solution faster than the exact methods. However, it does not give any guarantee for finding the optimal solution. The heuristics used for the VRP problem can be classified into two main classes, these are classical heuristics which was developed between year 1960 and 1970 and metaheuristics (modern heuristics) (Toth and Vigo 2002).

### 3.3.1 Classical heuristics

The classical heuristics produce typically good solutions within relatively short computation time. This is when performing a relatively limited exploration of the search space. Classical heuristics can be divided into three different categories; constructive heuristics, improvement heuristics and two-phase heuristics. The constructive heuristics keep an eye on the solution cost when gradually building a feasible solution. An example of a constructive heuristic is Clark and Wright algorithm (savings algorithm), this is one of the best known heuristics for the VRP (Toth and Vigo 2002). Improvement heuristics for the VRP use search mechanism to try to improve a feasible solution, this can be done on a single-route or on a multiroute (Toth and Vigo 2002). Two-phase heuristics is a combination of finding a solution in two different phases, clustering and routing. Some of the algorithms are Fisher and Jaikumar algorithm (which will be explained in more detail below) and Christifides, Mingozzi and Toth algorithm.

## Fisher and Jaikumar algorithm

Fisher and Jaikumar presented the cluster-first, route-second heuristic in 1981 (Fisher and Jaikumar 1981). The Fisher and Jaikumar heuristic will always find a feasible solution if one exists. It is also easy to adapt the heuristic to handle additional problems like multiple depots, multiple time periods, capacity constraints and constraints on duration of the routes. The solution quality outperforms heuristics like Clark and Wright and Christofides. In tests done by Fisher and Jaikumar, their heuristic found the best solution in 9 out of 12 problems, and on average it provided the best solution value. (Fisher and Jaikumar 1981).

The heuristic consists of two parts, the first part is to locate the seeds and construct clusters around them. This is done in order to minimize the distance between the customers and the seeds and at the same time it has to satisfy the capacity constraint. The second part is to use the TSP to determine a route for each cluster (Laporte 2009). Fisher and Jaikumar solve a Generalized Assignment Problem (GPA) to form the clusters.

A seed is a specific customer node that needs to be visited by a specific vehicle. There will be the same number of seed nodes as vehicles. The seed nodes can be chosen randomly, but to get a good solution, some sense should be used when deciding the nodes. This can be done by selecting nodes that probably not would be served by the same vehicle in the optimal solution. That could be nodes located geographically far from each other, or nodes that have large demands, so that it would violate the capacity if they were served by the same vehicle.

The steps of the algorithm are:
Step 1: The seed selection. Choose seed vertices $j_{k} \in V$ to initialize each cluster $k$.
Step 2: Allocation of customers to seeds. Compute the cost $d_{i k}$ of allocating each customer $i$ to each cluster $k$ as $d_{i k}=\min \left\{c_{0 i}+c_{i j_{k}}+c_{j_{k} 0}, c_{0 j_{k}}+c_{j_{k} i}+c_{i 0}\right\}-\left(c_{0 j_{k}}+c_{j_{k} 0}\right)$.

Step 3: Generalized assignment. Solve a GAP with costs $d_{i j}$, customer weights $q_{i}$, and vehicle capacity $Q$.
Step 4: TSP solution. Solve a TSP for each cluster corresponding to the GAP solution. (Toth and Vigo 2002, p.117).

## The Generalized Assignment Problem

Let $n$ be the number of tasks to assign to $m$ agents and define $N=\{1,2, \ldots, n\}$ and $M=\{1,2, \ldots, m\}$. The parameter $c_{i j}$ is the cost of assigning task $j$ to agent $i$.

The parameter $r_{i j}$ is the amount of resource required for task $j$ by agent $i$. Let $b_{i}$ be the resource units available to agent $i$.

The decision variable, $X_{i j}$, is equal to one if task $j$ is assigned to agent $i$.

$$
\begin{equation*}
\min \sum_{i=1}^{m} \sum_{j=1}^{n} c_{i j} \cdot X_{i j} \tag{8}
\end{equation*}
$$

St.
$\sum_{j=1}^{n} r_{i j} \cdot X_{i j} \leq b_{i} \quad \forall i \in M$

$$
\begin{array}{ll}
\sum_{i=1}^{m} X_{i j}=1 & \forall j \in N \\
X_{i j}=0 \text { or } 1, & \forall i \in M, j \in N
\end{array}
$$

The main objective (8) is to minimize the total cost of the assignment. Constraint (9) enforces resource limitation and constraint (10) ensures that each agent gets exactly one task. The variables domain are displayed in constraint (11) (Nauss 2006 ).

### 3.3.2 Metaheuristics

Metaheuristics can be seen as a natural improvement of the classical heuristics, they perform a deep exploration of the most promising regions of the solution space. The quality of the solution is higher when using metaheuristics, at the same time the computation time increase (Toth and Vigo 2002). Metaheuristics can be divided into local search, population search and learning mechanisms. Tabu search and simulated annealing are local search algorithms. These algorithms start the search from an initial solution and move to another solution in the neighborhood (Laporte 2009). Population search, like Genetic algorithms, mimics the process of the natural selection (Toth and Vigo 2002).

### 3.4 Aircraft routing

In this section of the paper, some of the articles that are written on the subject of aircraft routing will be presented.

In an article written by Desaulniers et al. (1997), the authors consider the daily aircraft routing and scheduling problem (DARSP). The objective is to maximize the profit derived from the aircraft of a heterogeneous fleet when determining daily schedules. In this article they use two different models; in the first they define a binary variable for each possible schedule for an aircraft type giving rise to a large Set Partitioning-type problem. In the second model they present a binary variable representing the possible connection between two flight legs performed by a particular aircraft. This is a time constrained multicommodity network flow formulation. Both models are integer-programming models and they are solved by branch-and-bound. They use this definition of DARSP: "Given a heterogeneous aircraft fleet, a set of operational flight legs over a one-day horizon, departure time windows, duration and costs/revenues according to the aircraft type for each flight leg, find a fleet schedule that maximizes profits and satisfies certain additional constraints." (Desaulniers et al. 1997, p. 842).

Pita, Adler and Antunes (2014) present a socially oriented flight scheduling and fleet assignment optimization model (SFSFA). The objective function is to minimize the total social costs. The aim of the paper is to assist "the public authorities in the design of subsidized air transport network, with specific analysis of the requirements such network should meet with respect to the level of service offered to passengers" (Pita, Adler, and Antunes 2014,17). They analyze the different results obtained from the model from the perspectives of passengers, airline, airport and government to compare the service levels and the funding. The model considers airport cost and revenues, travel time, passenger demand and social welfare. They also consider the PSO requirements. Their main research question is: "How should an air transport network that is operated as a monopolistic public service be organized such that network costs are minimized?" (Pita, Adler, and Antunes 2014,18). The SFSFA-model is used on a single day that is divided into timeperiods, and on routes with up to two intermediate stops. The authors have used their model on the PSO network in Norway (Pita, Adler, and Antunes 2014).

### 3.5 Other relevant articles

In an article written by Daniel Karapetyan and Abraham P. Punnen (2013) , the authors present an integer programming model for the ferry scheduling problem (FSP). The aim of the FSP is to find a route and a schedule for the ferries, so that the demand at the ferry ports is satisfied, while minimizing operations cost and passenger dissatisfaction. In the model, they are given a set of ports, a set of ferries and a planning horizon. In their model, they also include new constraints such as passenger transfers, crew scheduling and loading/unloading. They were able to make a model that gives a good solution in 12 hours, when using CPLEX 12.4 (Karapetyan and Punnen 2013).

In a report conducted by Møreforskning about the tendering arrangements in northern Norway, there is also a part about modeling (Bråthen et al. 2015). This part was called "A mathematical model for planning of aviation routes" and is written by Johan Oppen. The model that is presented is based on an extension of the Vehicle Routing Problem, where they take into consideration factors like cost, time and capacity related to the aircraft and the flight. The objective function is to minimize the total cost, this includes the sum of variable costs for all legs flown and the fixed cost for using the aircraft.

### 4.0 Analysis

Before building the model, it is important to get an overview over all the factors that can affect a flight. The factors we consider as relevant for our problem will be analyzed in this chapter.

### 4.1 Modeling choices and assumptions

This section will present the choices and assumptions taken in this thesis. Routing of aircraft is a complex problem, and the routes can be influenced by many factors. To make the problem easier to handle, all these factors needs to be evaluated and the problem needs to be limited.

### 4.1.1 Uncertainty

The weather, human errors and mechanical errors are all different types of uncertainty. A flight can be affected by any of these, some more often than others. The weather is a big uncertainty factor, especially in northern Norway where the weather often changes. Snow, wind and freezing temperatures can all delay a planned flight. We have only mentioned some of the uncertainty factors, the reason is that we will not include any of these in our model. If the uncertainty were to be included in the model, both the computation time and the complexity would increase. That is why the model in this thesis are going to be deterministic.

### 4.1.2 Planning horizon

The planning horizon is set to be one day, and it is assumed that the routes are the same for each day. More specific, the planning horizon is going to be between 05:00 and 24:00. The reason for choosing this horizon is that most of the flights happen during these hours. In addition, limiting the planning horizon will make the problem easier to handle.

This means that an aircraft cannot leave the depot before 05:00 in the morning, and it has to be back at the depot before 24:00 in the evening.

### 4.1.3 Airports

We wanted to explore how our model would handle routes with multiple short legs. Since most of the chained air trips in Norway are carried out in the northern parts, this will be the focus area of this thesis. The area consists of 28 airports, which includes three airports in Trøndelag. In addition, are some of the smallest airports excluded, this is because they usually only handle helicopter traffic. Table 3 shows the airports included in this thesis.

The depots are where the aircraft will stay overnight and where the maintenance will happen. The depots are chosen based on size and location of the airports. Why and how the specific depots are chosen will be explained in more detail in chapter 6.2.

### 4.1.4 Aircraft

There will be a number of available aircraft, and the model will decide how many aircraft to use to cover the visit frequency. The size of the aircraft is not important since the visit frequency is used instead of the passengers demand.

### 4.1.5 Visit frequency

Visit frequency will be used instead of passenger demand. The visit frequency is the number of landings on a specific airport during the time horizon, and this frequency will be based on the size of the airports. The visit frequency does not take into consideration where the passengers are travelling to and from.

### 4.1.6 Cost

The fixed and variable cost will be considered in this thesis. The variable costs are the cost of flying, only the fuel costs will be included here. In addition, there are costs of using an
airport and the services that the airport provides. Those are included in the fixed costs. The fixed cost of using an airport consist of: take-off charge, terminal fee, air navigation fee, passenger and security charges (Avinor 2016b). These costs are fees that the airlines have to pay to Avinor, when using an airport owned by Avinor. The Norwegian Ministry of Transport and Communications regulates these fees.

### 4.1.7 Roundtrips

The aircraft will have a maximum number of times they can fly out of the depot to service a route. This is implemented to allow an aircraft to fly more than one roundtrip. Each of the roundtrips have a time limit of 32 time periods, which is equal to 8 hours. The reason for choosing this number was that the flight duty period for short haul flights are maximum 10 hours. Because our maximum time for a roundtrip does not include the time the aircraft is on the ground between flights, it is calculated some slack into the time limit. Based on this, we have chosen to limit the number of roundtrips per aircraft to a maximum of three trips per time horizon. If an aircraft flies the maximum duration of a roundtrip, it only has time to travel two roundtrips. The possibility that an aircraft uses 32 time periods on a roundtrip is small, as it will be a limit on how many airports an aircraft can visit during a roundtrip.

### 4.2 Parameters

The parameters that will be used in the model will be presented in this section. The parameters will be described in more detail later in this thesis.
As mentioned before all our parameters are deterministic.

- Visit frequency
- Distance
- Travel time
- Time periods
- Number of roundtrips
- A big number
- Service time at the depot
- Maximum time of one roundtrip
- Maximum number of landings per roundtrip

### 5.0 Model

In this chapter the model will be presented and explained in detail. It is used a two-phased approach to solve the problem. The reason for this is that it is difficult to make a model that uses exact methods when handling a multiple-depot VRP with 28 airports.

In the first phase it will be used an algorithm to divided the airports into different clusters. Each cluster will have a depot. The second phase will be to make routes for the clusters, this will be done by using our modified model for the VRP.

### 5.1 First phase mathematical formulation

The first phase will present the method used to divide the airports into different clusters.

To make clusters out of the airports, the algorithm by Fisher and Jaikumar is used. In this thesis the objective of this algorithm is to minimize the total distance travelled between the depot and the airports. Another possibility would be to minimize the travel time or the cost. The goal of the clustering model is to connect the airports to the depots.

The first step is to choose seed-nodes, one for each cluster. The next step is to calculate the added distance when connecting the airports to the seed nodes. The model described in 5.5.1 will be used to minimize the added distance and find the clusters. This model is based on the model for the generalized assignment problem, presented in 3.3. When the clusters are found, the VRP model presented in 5.2 will be used to make the routes for each of the clusters.

The Fisher and Jaikumar heuristic is originally meant for problems with one visit to each customer, but it is possible to use in a problem that allows multiple visits to a customer on a route. The GAP will connect each node to a seed node and the model for the VRP will determine the routes and the number of visits.

### 5.1.1 F\&J model

Let N be a set of nodes and P a set of aircraft. The parameter $a d_{i p}$ is the added distance of connecting node $i$ to aircraft $p$. The binary variable $Y_{i p}$ is equal to 1 if node $i$ is connected to aircraft $p$.

In order to calculate the added distance from each depot, we used a version of the calculation presented in 3.3. The formula presented in the theory can be written as $a d_{i p}=$ $c_{i j_{k}}+c_{i 0}-c_{0 j_{k}}$. In our specific problem, the seed nodes also are the depots, so we can change the formula to $a d_{i p}=2 * c_{i j_{k}}$. That means the added distance of connecting an airport to a depot is the distance from the depot to the airport and back. This way, we ensure that all airports will be connected to the nearest depot.

$$
\begin{equation*}
\min \sum_{i \in N} \sum_{P \in P} a d_{i p} \cdot Y_{i p} \tag{12}
\end{equation*}
$$

St.
$\sum_{p \in P} Y_{i p}=1$
$i \in 1 . . N$
$Y_{i p} \in\{0,1\}$
$i \in 1 . . N, p \in P$

The main objective (12) is to minimize the total added distance. Constraint (13) ensures that each node is linked together with only one aircraft. The variables domain are displayed in constraint (14).

### 5.2 Second phase mathematical formulation

In this part, the mathematical model for the modified VRP will be presented. The notation used in the model will be presented first, then the model and the constraints, and at last the different extensions.

## Notation:

Let $\mathcal{A}$ be a set of airports, and $\mathcal{P}$ be a set of aircraft. As mentioned before, we only use one aircraft size. In addition, all the aircraft needs to have a "home-base" that they operate from. We have decided that the depot should be the base.

Let $\mathcal{N}=0,1, \ldots, N$ be a set of nodes, where $0 \in \mathcal{N}$ is the depot and $N \in \mathcal{N}$ is the copy of the depot. Let $A R C$ be the set of arcs $(i, j) \in A R C$, which represents all the arcs in the network. The distance is given by $d_{i j}$ and the flying time is $t t_{i j}$.

Let T be the time periods, each time period is equal to 15 minutes and there are 76 time periods. Each aircraft have to stay at an airport for one period between arrival and departure. Let R be the number of roundtrips. When the aircraft has finished one roundtrip it has to stay at least a given number of time periods $s d$ in the depot before it leaves for the next roundtrip.

The parameter Tmax gives the travel time between the two nodes that are located furthest apart from each other. This parameter is used to make sure that the routes end before the time horizon is over. We have the parameter $v f_{j}$, which is the visit frequency for airport $j$. The parameter M represents a large number.

Let $l$ be the maximum number of landings during one roundtrip. The maximum number of allowed landings at each airport for each aircraft per roundtrip is represented by la.

We have decided to operate with two types of binary routing variables. $X_{i j p t r}$ is equal to 1 if aircraft $p$ leaves airport $i$ to go to airport $j$ in time period $t$ on roundtrip $r, 0$ otherwise. $Y_{i j p t r}$ will take the value 1 if aircraft $p$ arrives at airport $j$ from airport $i$ in time period $t$ on roundtrip $r, 0$ otherwise.

\end{array}
$$

### 5.2.1 Model description

The objective function (15) is to minimize the total distance travelled for all aircraft during the time horizon.

Constraint (16) says that in order to leave node $i$, the aircraft has to start the trip by leaving the depot and go to some node $j$. Constraint (17) is a continuity constraint for the depot. The constraint ensures that the number of aircraft leaving the depot is equal to the number of aircraft arriving at the depot at the end of a roundtrip. Continuity constraint (18) make sure that the number of aircraft arriving at a node is the same number as aircraft leaving that exact node. It ensures balance for all nodes, aircraft and roundtrips. Constraint (19) says that the number of visits at an airport should be larger or equal to the required visit frequency.

Constraint (20) is implemented to ensure the right order of the roundtrips, which says that if the aircraft are to fly roundtrip two, then roundtrip one have to be flown first. Constraint (21) prevents the same aircraft from leaving the depot more than one time during each roundtrip.

Constraints (22) and (23) connects the two types of binary routing variables. Constraint (22) ensures that if the aircraft leaves node $i$ then it has to arrive at node $j$ a given number of time periods after leaving node $i$. Constraint (23) make sure that if an aircraft arrives at
an airport, the same aircraft has to leave that airport one time period later. Constraint (24) is a time constraint, ensuring that no arcs are travelled after the time horizon is over.

Constraint (25) says that no aircraft can travel on any of the arcs $(i, j)$ during the last time periods. When saying that the time for starting the last leg cannot be after T-Tmax, the constraint makes sure that the last leg travelled will end before the time period is over. Tmax is the longest travel time between two airports in each cluster. This means that the legs with shorter travel time could have flown later than T-Tmax, and the aircraft would still have made it back to the depot before the end of the time horizon.

Constraint (26) is a "Big M"-constraint, the main goal is to ensure that the time of the roundtrips are correct. The constraint says that the time of departure for the next roundtrip should be later than the time of arrival included the service time at the depot.

The variables domain are given in constraints (27) and (28).

### 5.2.2 Extensions

This part will describe the different extensions of the model.

The first extension is a time-constraint.

$$
\begin{equation*}
\sum_{(i, j) \in A R C} \sum_{t=1}^{T} X_{i j p t} * t t_{i j} \leq R \max \quad \quad p \in P, r \in 1 . . R \tag{29}
\end{equation*}
$$

Constraint (29) ensures that the active flight time does not exceed a given number of time periods. The active flight time is the time the aircraft is in the air. In the first chapter we presented the different regulations concerning the flight duty period (FDP), we included this constraint to make the model more realistic.

$$
\begin{equation*}
\sum_{t=1}^{T} \sum_{(i, j) \in A R C} X_{i j p t r} \leq l a \quad p \in P, r \in 1 . . R, j \in A \tag{30}
\end{equation*}
$$

This constraint (30) ensures that during one roundtrip, the aircraft can only land a given number of times at each airport.

$$
\begin{equation*}
\sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r}+\sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} Y_{i j p t r} \leq 1 \quad t \in 1 . . T, j \in A \tag{31}
\end{equation*}
$$

Constraint (31) ensures that no aircraft lands and take off in the same time period at the same airport.
$\sum_{(0, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{0 j p t r}+\sum_{(i, N)} \sum_{p \in P} \sum_{r=1}^{R} Y_{i(N) p t r} \leq 1 \quad t \in 1 . . T$
Constraint (32) ensures that no aircraft lands and take off at the depot in the same time period.

$$
\begin{equation*}
\sum_{t=1}^{T} \sum_{(i, j) \in A R C} X_{i j p t r} \leq l \quad p \in P, r \in 1 . . R \tag{33}
\end{equation*}
$$

This constraint (33) limits the total number of landings for each aircraft on each roundtrip.

$$
\begin{equation*}
\sum_{t=1}^{20} \sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r} \geq 1 \quad j \in A \tag{34}
\end{equation*}
$$

Constraint (34) ensures that at least one aircraft leaves each airport before 10:00 in the morning (which is equal to time period 20).

$$
\begin{equation*}
\sum_{t=48}^{T} \sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r} \geq 1 \quad j \in A \tag{35}
\end{equation*}
$$

Constraint (35) ensures that there is at least one aircraft leaving each airport after 17:00 in the afternoon (equal to time period 48).

### 5.3 Data collection

The data used in this thesis is secondary data collected from different sources. This section will present the data that will be used when solving the model. The data presented is based on the factors we analyzed earlier in the thesis. The data consists of visit frequency, service time, costs, geographical distance, and the time it takes to travel between two particular airports.

### 5.3.1 Distances

The distances between the airports are based on a direct line measured in kilometers. The data was collected from a website called Distance24. This website gave the direct distance between all the airports included in the thesis (Distance 24 2016). Table 5 show the distance used when testing the model.

| Distance |  |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  |  | 1 | 2 | 3 | 4 | 5 | 6 |
| Trondheim | 1 |  | 127 | 165 | 247 | 299 | 307 |
| Namsos | 2 | 127 |  | 46 | 120 | 172 | 181 |
| Rørvik | 3 | 165 | 46 |  | 85 | 142 | 144 |
| Brønnøysund | 4 | 247 | 120 | 85 |  | 58 | 61 |
| Mosjøen | 5 | 299 | 172 | 142 | 58 |  | 33 |
| Sandnessjøen | 6 | 307 | 181 | 144 | 61 | 33 |  |

Table 5: Distance data used when testing the first model

The overview over the rest of the distances can be found in Appendix A.

### 5.3.2 Travel time

The travel time and distance of the routes that are operated today was collected from Widerøe. The different routes are divided into four groups according to the length: from 0 to 99 kilometers, 100 to 249 kilometers, 250 to 399 kilometers and routes that are longer than 400 kilometers. From these four groups and the real data provided by Widerøe it was calculated a factor, this factor is the average number of kilometers travelled per minute. To get the right travel time on the different legs, the real distance between the airports was divided by the right factor according to the length of the route. After finding the travel time in minute this was changed into time periods of 15 minutes. The groups and the average number of kilometers per minute can be found in table 6 , and the calculations can be found in appendix B. The overview over all the distances can be found in appendix A. Example: lets say that there is a route that is 299 kilometers, to find the time it takes to travel the
route we took the distance 299 and divide this on the factor 5,7 which is equal to 53 minutes.

| Distance <br> $(k m)$ | Average <br> km/min | Median | $\sigma$ |
| :--- | ---: | ---: | ---: |
| $400->$ | $\mathbf{6 , 4}$ | 5,8 | $\mathbf{1 , 2}$ |
| $250-399$ | $\mathbf{5 , 7}$ | 5,9 | 0,7 |
| $100-249$ | $\mathbf{4 , 6}$ | 4,7 | 0,6 |
| $0-99$ | $\mathbf{3 , 0}$ | 3,0 | 0,7 |

Table 6: Kilometers per minute

In our model, it is used discrete time and one time period is equal to 15 minutes. The time horizon is from 05:00 to 24:00, which is equal to 76 time periods.

| Time periods |  |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  |  | 1 | 2 | 3 | 4 | 5 | 6 |
| Trondheim | 1 |  | 1 | 2 | 3 | 4 | 4 |
| Namsos | 2 | 1 |  | 1 | 1 | 2 | 2 |
| Rørvik | 3 | 2 | 1 |  | 2 | 2 | 2 |
| Brønnøysund | 4 | 3 | 1 | 2 |  | 1 | 1 |
| Mosjøen | 5 | 4 | 2 | 2 | 1 |  | 1 |
| Sandnessjøen | 6 | 4 | 2 | 2 | 1 | 1 |  |

Table 7: Travel time in periods
Overview over all the travel times can be found in appendix C.

### 5.3.3 Service time

The service time is defined as the time from an aircraft lands on an airport until it leaves the same airport. Included in this time is the unloading and loading of passengers and baggage, as well as cleaning and document handling.

We have analyzed the flights in northern Norway, and found that an aircraft on average uses between 10 to 25 minutes on the ground in between two flights. Based on that analysis, we have decided that the service time (time on the ground) should be one time period. When it comes to the service time at the depot, we have decided that it should be at least three periods. Meaning that the aircraft have to stay in the depot for at least three time periods before leaving for the next roundtrip.

### 5.3.4 Visit frequency

The visit frequency indicates how many times an airport should be visited during the time horizon. The visit frequency will be based on the size of the airports. Large airports should be visited more times than smaller airports. The visit frequency will be used as an indicator to find the distribution in landings between the airports.

The visit frequency can be found in appendix D.

### 5.3.5 Costs

The cost is divided into variable and fixed costs. The variable cost will consist of the fuel cost. This cost is calculated from the fuel consumption and the fuel price as shown below.

Fuel consumption: 2.3 liter per kilometer (FlightRun 2015).
Fuel price: 2.4 NOK per kilometer (index mundi 2016).
Fuel cost: 2.3 liter/km*2.4 NOK/liter $=5.52$ NOK/km

The fixed cost includes the costs concerning the use of an airport, the costs of handling the aircraft, as well as the safety cost. The fees included in our calculations are: take-off charge, terminal fee, air navigation fee, passenger charge and security charge. The takeoff, terminal and air navigation fees are all based upon the size of the aircraft. The take-off charge is also based on the size of the airport from where the aircraft is leaving. From the international and national airports, the cost of take-off is 64 NOK * MTOW, which means the maximum takeoff weight. The regional airports have a $30 \%$ discount. A Dash 8 aircraft is used as a basis in the calculations. This aircraft has a maximum take-off weight of 17 tons. The Dash 8 is the same aircraft as Widerøe operate on some of the routes today.

The terminal fee is based on the number of service units and the size of the airport. A service unit is calculated as (MTOW/50) ${ }^{\wedge} 0,7$. For Trondheim the cost is 1787.43 NOK per service unit, for all the other airports it is 1251.20 NOK per unit. The air navigation fee is 381.42 NOK per service unit (Avinor 2016b).

The safety and the passenger cost are both based on the number of passengers in the aircraft. The safety charges are 56 NOK per passenger and the passenger charge is 54

NOK per passenger (Avinor 2016b). To calculate the passenger and safety charges per trip, we have assumed a $60 \%$ coverage, as it is not normal that every aircraft is fully booked.

Total cost will consist of: take-off fee + safety fee + passenger fee + terminal fee + air navigation fee + fuel cost.

The safety, passenger and the air navigation fee are the same for each airport and can be excluded from the calculation. Then the calculations of the costs of travelling between airports, based on which airport you are travelling from, are as following:

| Total costs |  |
| :---: | :--- |
| Trondheim | $1927.97+5.52 * \mathrm{~km}$ |
| Troms $\varnothing$ and Bodø | $1675.98+5.52 * \mathrm{~km}$ |
| Other | $1349.58+5.52 * \mathrm{~km}$ |

Table 8: Total cost of travelling from the different airports.

A detail explanation of the calculation can be found in appendix E, and an overview of travelling cost between airports can be found in Appendix F.

### 6.0 Computational experiments

In this part, the method used to solve the problem will be presented, as well as the different scenarios used. Since the problem consist of 28 airports with multiple landings on each airport, the Fisher and Jaikumar algorithm will be used to divide the different scenarios into clusters. The results of the clustering will be presented and explained later in this chapter.

There will also be a part where the model will be tested and analyzed, to see if the model needs to be changed or if more extensions need to be implemented. After the test the new modified model will be used on the different clusters.

### 6.1 Method

To solve the problem the AMPL modeling language will be used and the problem will be solved through a Gurobi solver, which are provided by the NEOS server. The reason why an Internet based solver is used is because the solver on the school computers have a relatively low capacity, and the NEOS server gives us a shorter computation time.

AMPL is an algebraic modeling language used for large-scale optimization and mathematical programming problems (Fourer, Gay, and Kernighan 2003). We have learned this language during our master program.
"The NEOS Server is a free internet-based service for solving numerical optimization problems" (Wisconsin Institutes for Discovery 2016a). NEOS can handle relatively large problems, but it will terminate jobs that are not finished in 8 hours without giving out any results. This is why we have chosen to use a time limit of maximum 7 hours when testing the model. The research organization that operate the website, Morgridge Institute of Research (MIR) does not guarantee that the output of the service is the correct result or that it will be completed (Wisconsin Institutes for Discovery 2016b). The NEOS server does also have a memory limitation of 3 GB RAM. In table 9 we have provided an overview over the hardware specifications for the NEOS server used in this thesis.
neos-7 is a Dell PowerEdge R430 server with the following configurations:

- CPU - 2x Intel Xeon E5-2698 @ 2.3 Hz (32 cores total), HT Enabled
- Memory - 192 GB RAM
- Disk - 4x 300G SAS drivers setup in RAID5
- Network - $1 \mathrm{~Gb} / \mathrm{s}$ Ethernet

Table 9: Hardware specifications for the NEOS solver

### 6.2 Scenarios

We have decided to use different numbers of seed nodes, these are divided into three different groups: one with three seed nodes, one with four seed nodes and the last one with five seed nodes. For each of these groups we will have two different scenarios, meaning that there will be different combination of seed nodes in each of the two scenarios. One of the scenarios in each group is based only on the location of the seed nodes. The other
scenario in the group will be a more realistic combination of seed nodes. This is done to compare the different outcomes.

In the beginning of the clustering chapter, it was mentioned that the clustering could be based on minimizing either the total distance, total time or total cost. It is not necessary to use anything else than distance since both the time and the cost are dependent on the distance, and the clusters would be the same. Instead, the total cost and time are displayed for each of the clusters and the scenarios used in the model.

The different scenarios will be presented in the next part of this chapter. In addition, will it be explained why these specific seed nodes are chosen.

### 6.2.1 Scenario 1: Trondheim, Bodø, Tromsø

Trondheim, Bod $\varnothing$ and Troms $\varnothing$ are natural to choose when only choosing three seed nodes in the northern part of Norway. This is based on the geographical location and the number of people living in the area surrounding the airports. These three towns are also the capital of their region, and there are institutions like hospitals and universities located there.

### 6.2.2 Scenario 2: Bodø, Tromsø, Kirkenes

In this scenario, Kirkenes replaces Trondheim. The reason for this is that Kirkenes is in Finnmark, and by placing one of the seed nodes there we can reach many of the smaller airports located in the area. We excluded Trondheim as a seed node because in our data set we only had three airports in Trøndelag. There was no need of having Trondheim as a seed node when considering the total distance travelled. In a real life situation, this would not be an optimal choice since Trondheim is connected to the rest of Norway, and the demand in the region is high.

Even thought the county administration in Finnmark is located in Vadsø, it is more natural to choose Kirkenes as the seed node in this area. The reason for this is that Kirkenes is a much larger airport and it have direct connections to Oslo.

### 6.2.3 Scenario 3: Trondheim, Bodø, Tromsø, Kirkenes

In this scenario there are four different seed nodes. These are Trondheim, Bodø, Troms $\varnothing$ and Kirkenes. These seed nodes are chosen based on the average domestic demand at the airports and the distances between the chosen seed nodes. In addition, the seed nodes are located in different regions: Trøndelag, Nordland, Troms and Finnmark.

This scenario is similar to the situation today, where all the seed nodes are located relatively far from each other. In addition, based on the demand, they are the four largest airports in the northern part of Norway.

### 6.2.4 Scenario 4: Trondheim, Brønnøysund, Tromsø, Lakselv

In this scenario we have only considered the location of the airports, but this would most likely not work in the real life. Trondheim is chosen as a seed node since this airport covers the airports furthest south in the data area. Brønnøysund is chosen because it is a medium sized airport in between Trondheim and Tromsø. Tromsø is included as a seed node since it is natural to choose when considering the location. Lakselv is chosen as a seed node because it is located in the middle of Finnmark.

### 6.2.5 Scenario 5: Trondheim, Mosjøen, Bodø, Tromsø, Lakselv

In this scenario we have used the same strategy as in scenario 4, where all the seed nodes are chosen based only on the geographical location. The size of the airports are not considered, neither are the domestic demand of the different airports. Trondheim, Troms $\varnothing$ and Lakselv are chosen for the same reason as mentioned in scenario 4. In this scenario we have chosen to have two seed nodes between Troms $\varnothing$ and Trondheim, the best choice based on the distance was then to choose Bodø and Mosjøen.

### 6.2.6 Scenario 6: Trondheim, Bodø, Evenes, Tromsø, Kirkenes

When choosing the seed nodes for this scenario factors like size of the airports, number of visits each day and the geographically location was taken into account. In this scenario, it is only Evenes that has not been chosen as a seed node in any of the previous scenarios. Evenes is chosen because it is a large sized airport located in between Tromsø and Bodø.

### 6.3 Result of clustering

The different clusters and scenarios are presented in table 10. In the table, the seed nodes are displayed with bold font. The model created the clusters by minimizing the added distance connecting the airports and the depot.

|  | Scenario 1 | Scenario 2 | Scenario 3 | Scenario 4 | Scenario 5 | Scenario 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Cluster 1 | Trondheim, Namsos, Rørvik | Trondheim, Namsos, Rørvik, Brønnøysund, Mosjøen, Sandnessjøen, Mo i Rana, Bodø, Leknes, Svolvær, Stokmarknes | Trondheim, Namsos, Rørvik | Trondheim | Trondheim, Namsos | Trondheim, Namsos, Rørvik |
| Cluster 2 | Brønnøysund, Mosjøen, Sandnessjøen, Mo i Rana, Bodø, Leknes, Svolvær, Stokmarknes | Narvik, Evenes, <br> Andøya, <br> Bardufoss, <br> Tromsø, <br> Sørkjosen, Alta, Hasvik, Hammerfest | Brønnøysund, Mosjøen, Sandnessjøen, Mo i Rana, Bodø, Leknes, Svolvær, Stokmarknes | Namsos, Rørvik, <br> Brønnøysund, <br> Mosjøen, <br> Sandnessjøen, <br> Mo i Rana, Bodø | Rørvik, <br> Brønnøysund, Mosjøen, <br> Sandnessjøen, <br> Mo i Rana | $B r ø n n ø y s u n d$, Mosjøen, Sandnessjøen, Mo i Rana, Bodø, Leknes |
| Cluster 3 | Narvik, Evenes, <br> Andøya, <br> Bardufoss, <br> Tromsø, <br> Sørkjosen, Alta, Hasvik, <br> Hammerfest, <br> Lakselv, <br> Honningsvåg, <br> Mehamn, <br> Berlevåg, <br> Båtsfjord, Vard $\varnothing$, <br> Vads $\varnothing$, Kirkenes | Lakselv, Honningsvåg, Mehamn, Berlevåg, Båtsfjord, Vard $\varnothing$, Vads $\varnothing$, Kirkenes | Narvik, Evenes, <br> Andøya, <br> Bardufoss, <br> Tromsø, <br> Sørkjosen, Alta, Hasvik, <br> Hammerfest | Leknes, Svolvær, Stokmarknes, Narvik, Evenes, Andøya, Bardufoss, Tromsø, Sørkjosen | Bod $\varnothing$, Leknes, Svolvær, Stokmarknes | Svolvær, Stokmarknes, Narvik, Evenes, Andøya |
| Cluster 4 |  |  | Lakselv, Honningsvåg, Mehamn, Berlevåg, Båtsfjord, Vard $\varnothing$, Vadsø, Kirkenes | Alta, Hasvik, Hammerfest, Lakselv, Honningsvåg, Mehamn, Berlevåg, Båtsfjord, Vardø, Vadsø, Kirkenes | Narvik, Evenes, <br> Andøya, <br> Bardufoss, <br> Tromsø, <br> Sørkjosen | Bardufoss, <br> Tromsø, <br> Sørkjosen, Alta, Hasvik, Hammerfest |
| Cluster 5 |  |  |  |  | Alta, Hasvik, Hammerfest, Lakselv, Honningsvåg, Mehamn, Berlevåg, Båtsfjord, Vard $\varnothing$, Vadsø, Kirkenes | Lakselv, Honningsvåg, Mehamn, Berlevåg, Båtsfjord, Vardø, Vads $\varnothing$, Kirkenes |

Table 10: Overview over the scenarios and the clusters

By analyzing table 10 , we see that the difference between scenario 1 and 2 is that the airports in scenario 2 is more evenly spread among the seed nodes in the clusters. Cluster 3 in scenario 1 contains 17 airports and cluster 1 in the same scenario only contains three airports. This imbalance can make it harder to solve the modified VRP for the clusters that contains many airports.

Both scenario 3 and 4 does have four seed nodes. When Trondheim and Brønnøysund both are chosen as seed nodes same as in scenario 4, Trondheim ends up alone. The reason for this is that the other airports nearest to Trondheim are located closer to Brønnøysund than Trondheim.

In the scenarios with five seed nodes, the airports are more evenly spread among the seeds. There are still some clusters that are bigger than others, one example of this is that in both scenario 5 and 6 cluster 5 is the biggest cluster. These clusters does both have a seed node located in Finnmark. In our data, Finnmark is the area with the most airports located relatively close to each other.

When analyzing the results from the clustering and the routes provided by the modified model, it is important to evaluate if it is possible to implement these routes in the real life. It is also important that the seed nodes are located in a large city, which houses institutions like hospital, university and the county administration.

### 6.4 Testing the modified VRP model

To explore how the model behaves and if it gives a feasible solution, we have to start with a relatively small problem. It is easier to find the mistakes when using a smaller amount of data. The test will be used to figure out which combination of constraints that fits our problem the best. The results from this test will be used to build the model that we will use throughout the thesis.

First, the data used to test the model will be presented, after that the model will be tested with different constraints.

| Visit frequence: |  |
| :--- | :--- |
| Namsos | 3 |
| Rørvik | 2 |
| Brønnøysund | 4 |
| Mosjøen | 6 |
| Sandnessjøen | 4 |
| Table 11: Visit |  |

Table 11: Visit
frequency

In the process of testing we focused on six airports. These airports were Mosjøen, Brønnøysund, Sandnessjøen, Rørvik, Namsos and Trondheim (which represented the depot). The distance data and the time period data are the same as presented in chapter 4 . The visit frequency used in these tests are shown in table 11. We also specified that each aircraft only could travel maximum three roundtrips during the time horizon. The data presented in this part will be used on all the different tests conducted in this chapter.

Figure 5: Results from NEOS

We wanted to test the computation time of NEOS. To do this we used constraints (15) to (23) and changed the number of aircraft one by one. The reason why we did not use all constraints is that the computation time of the whole model is too long. To get a clearer picture of which number of aircraft that has the best computation time, we have decided that each aircraft only can fly one roundtrip. The results from this test are
shown in figure 5.

Figure 5 displays the computation time from NEOS. In this figure, we can see that it is a pattern. The computation time increases when more aircraft are added, but there are still some decreasing that cannot be explained. Example, the computation time when using seven aircraft is 7.19 , but when we use eight aircraft the time decreases to 3.47 .

From this test, the conclusion is that it is important to think about how many aircraft that will be used in the data. If there are excessively many aircraft available, the runtime of the model will increase. That is why we need to adjust the number of available aircraft in relation to the size of the clusters.

### 6.4.1 Test 1

In this test, the constraints from (15) to (28) is used. The extensions is not included. This test is done to explore how the output of the model is, and to see if there are any constraints missing. Table 12 presents the routes made by this model.

| Test 1 | Departure |  | Arrival |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Airport | Time | Airport | Time |
| Aircraft 1 <br> Roundtrip 1 | TRD |  | OSY | 8 |
|  | OSY |  | MJF | 12 |
|  | MJF | 13 | SSJ | 14 |
|  | SSJ | 15 | BNN | 16 |
|  | BNN | 17 | MJF | 18 |
|  | MJF | 19 | BNN | 20 |
|  | BNN | 21 | SSJ | 22 |
|  | SSJ | 23 | MJF | 24 |
|  | MJF | 25 | OSY | 28 |
|  | OSY | 29 | TRD | 31 |
| Aircraft 3 <br> Roundtrip 1 | TRD | 24 | OSY | 23 |
|  | OSY | 27 | RVK | 28 |
|  | RVK | 29 | MJF | 31 |
|  | MJF | 32 | BNN | 33 |
|  | BNN | 34 | SSJ | 35 |
|  | SSJ | 36 | MJF | 37 |
|  | MJF | 38 | SSJ | 39 |
|  | SSJ | 40 | BNN | 41 |
|  | BNN | 42 | MJF | 43 |
|  | MJF | 44 | RVK | 46 |
|  | RVK | 47 | TRD | 50 |

Table 12: Routes from test model 1

The output from test 1 shows that the model only chooses to use two aircraft and not any roundtrips. This is because the model does not have any limitations regarding the number of time periods used on each trip. Each aircraft visits at least nine airports. From the passengers perspective, this is not an optimal route. For example, if someone is supposed to travel from Namsos (OSY) to Trondheim, they have three options. They can take the aircraft leaving Namsos 07:15 (time period 9) or they can take the aircraft leaving Namsos 12:15 (time period 29). The catch is that those two options are the same aircraft on the same roundtrip and they will not arrive in Trondheim before $12: 45$. That is why the morning flight most likely will not be that popular, unless they are travelling to Mosjøen or Sandnessjøen. The last option is to travel by aircraft 3 which leaves Namsos 11:45 (time period 27) and arrives in Trondheim 17:30 (time period 50), after visiting nine other airports first.

When running the model and the data file in NEOS, it was discovered that the computation time was long. In order to find the reason for this, the model was tested with and without constraints (24), (25) and (26). These exact constraints were chosen since it was after implementing these constraints that the models computation time increased. In table 13, the different combinations of constraints are presented.

|  |  | Computation time |  | Comments |  | EOS |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | (seconds) : | Objective: | . | Job: | Password: |

Table 13: Testing the computation time

From these tests, we can see that it is a connection between the increased computation time and constraint (25). NEOS have terminated all the tests including constraint (25), when running the model with a time limit of 3 hours. The results came back with no basis, which means that the solver have not found enough proof to say that the solution is the optimal one. To see if it the model could find an optimal solution after a longer time, the time limit was increased to 7 hours. The result was still the same after 7 hours as it was after 3 hours.

Constraint (25) says that the aircraft cannot fly any of the arcs during the last time periods.

Constraint (25) cannot be excluded from the model, because this constraint make sure that there are no aircraft flying during the last periods of the time horizon. If the constraint were to be removed, aircraft would be flying out from airports and not reaching back to the depot before the time horizon was ending.

Conclusion from this test is that the constraint that increases the computation time, cannot be removed. This constraint is necessary in order to ensure that all the roundtrips will be finished and the aircraft are at their depot at the end of the time horizon. In the next test, a new constraint concerning the active flight time, which is the actual time the aircraft is in the air, will be implemented. This to make sure that each flight is no longer than it is supposed to, when considering the regulations.

### 6.4.2 Test 2

In this test, a new constraint (29), which is a time-constraint that says that the active flying time should not be more than a given number of time periods, will be included

$$
\begin{equation*}
\sum_{(i, j) \in A R C} \sum_{t=1}^{T} X_{i j p t} * t t_{i j} \leq R \max \quad p \in P, r \in 1 . . R \tag{29}
\end{equation*}
$$

Table 14 show the routes from the model used in test 2 . The result is almost the same as in test 1 . This time aircraft 3 and 4 are used. In this test, another problem occurs. The problem is that two aircraft seems to be at the exact same airports at the exact same time. Moreover, two aircraft cannot land or take-off at the same airport at the same time. Therefore, a new constraint that can prevent this from happening is implemented in the next test.

| Test 2 | Departure |  | Arrival |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Airport | Time | Airport | Time |
| Aircraft 3 Roundtrip 1 | TRD | 5 | RVK | 8 |
|  | RVK | 9 | MJF | 11 |

|  | MJF | 24 | OSY | 27 |
|  | OSY | 28 | TRD | 30 |

Table 14: Routes from test 2

The result shows that the constraint that was implemented regarding the active flight time did not make any difference. A possible reason could be that the maximum active flight time was set to be 8 hours. This is because the flight duty period for short-haul flights are maximum 10 hours. There is some slack, since the constraint only restricts the time the aircraft is in the air and not including the time an aircraft is at an airport. For example, when looking at the total time from aircraft 4 leaves the depot in time period 4, and until it arrives back at the depot in time period 30 , it has been 6 hours and 30 minutes. This do not exceed the time limit, and there is no reason to decrease this limit either, since the FTD is 10-12 hours.

### 6.4.3 Test 3

The next step is to implement constraints that prevents the aircraft to land more than one time at the same airport during one roundtrip. It is also implemented constraints saying that the aircraft cannot arrive or depart from the same airport or depot in the same time period. When testing these constraints, constraint (29) was removed and only the basic model and constraints (30), (31) and (32) was used.

$$
\begin{array}{ll}
\sum_{t=1}^{T} \sum_{(i, j) \in A R C} X_{i j p t r} \leq l a & p \in P, r \in 1 . . R \\
\sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r}+\sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} Y_{i j p t r} \leq 1 & t \in 1 . . T, j \in A \\
\sum_{(0, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{0 j p t r}+\sum_{(i, N)} \sum_{p \in P} \sum_{r=1}^{R} Y_{i(N) p t r} \leq 1 & t \in 1 . . T \tag{32}
\end{array}
$$

Constraint (30) limits the number of visits at each airport to one, for each aircraft per roundtrip. Constraint (31) ensures that no aircraft arrives or departs at the same airport in the same time period. Constraint (32) ensures that no aircraft arrives to or departs from the depot in the same time period.

| Test 3 | Departure |  | Arrival |  |

|  | OSY | 29 | MJF | 32 |
|  | MJF | 33 | SSJ | 34 |
|  | SSJ | 35 | BNN | 36 |
|  | BNN | 37 | RVK | 38 |
|  | RVK | 39 | TRD | 42 |

Table 15: Routes from test 3

Presented in table 15, are the routes provided by this test. More aircraft have been used, since the onelanding constraint has been included. This time the model choose to use aircraft $1,2,3$ and 4 , in addition does aircraft 1 and 3 have two roundtrips.

When implementing these constraints, the time limit is not a concern anymore. Still, constraint (29) will be included in the model that will be used in the next chapter. The reason for this is that the clusters might be bigger, and that can result in longer flights and the time limit might be exceeded.

The constraints work, since the aircraft no longer are at the same airports in the same time periods.

In addition, the aircraft does not land more than one time on the same airport during one roundtrip.

### 6.4.4 Test 4

The constraint tested in test 4 is constraint (33), which says that an aircraft on a roundtrip can maximum land four times. This constraint have been implemented to prevent too many stops during a trip, as we could see in test 1 and 2 , where each aircraft visits over nine airports. When testing this constraint, only the basic model and this extension will be used. This is to see how this extension will affect the solution.

$$
\begin{equation*}
\sum_{t=1}^{T} \sum_{(i, j) \in A R C} X_{i j p t r} \leq l \tag{33}
\end{equation*}
$$

$$
p \in P, r \in 1 . . R
$$

| Test 4 | Departure |  | Arrival |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Airport | Time | Airport | Time |
| Aircraft 1 <br> Roundtrip 1 | TRD | 18 | BNN | 22 |
|  | BNN | 23 | SSJ | 24 |
|  | SSJ | 25 | MJF | 26 |
|  | MJF | 27 | TRD | 32 |
| Aircraft 1 <br> Roundtrip 2 | TRD | 60 | MJF | 65 |
|  | MJF | 66 | SSJ | 67 |
|  | SSJ | 68 | MJF | 69 |
|  | MJF | 70 | TRD | 71 |
| Aircraft 2 | TRD | 17 | OSY | 19 |
| Roundtrip 1 | OSY | 20 | TRD | 22 |
| Aircraft 2 <br> Roundtrip 2 | TRD | 53 | OSY | 55 |
|  | OSY | 56 | RVK | 57 |
|  | RVK | 58 | OSY | 59 |
|  | OSY | 60 | TRD | 62 |
| Aircraft 3 <br> Roundtrip 1 | TRD | 34 | MJF | 39 |
|  | MJF | 40 | BNN | 41 |
|  | BNN | 42 | RVK | 43 |
|  | RVK | 44 | TRD | 46 |
| Aircraft 4 <br> Roundtrip 1 | TRD |  | MJF | 6 |
|  | MJF |  | SSJ | 8 |
|  | SSJ | 9 | MJF | 10 |
|  | MJF | 11 | TRD | 16 |
| Aircraft 4 <br> Roundtrip 2 | TRD | 26 | BNN | 30 |
|  | BNN | 31 | SSJ | 32 |
|  | SSJ | 33 | BNN | 34 |
|  | BNN | 35 | TRD | 39 |

As shown in table 16, the constraint works as it is supposed to do. This time aircraft 1,2,3 and 4 is used, in addition does aircraft 1,2 and 4 have two roundtrips each.

The constraint concerning the start time of the next roundtrip is correct.

Constraint (33) is working; none of the aircraft visits more than three towns, not including the depot.

Table 16: Routes from test 4

### 6.4.5 Test 5

In this test all the constraints and the extensions are implemented. In addition, there are two new constraints. The constraint maximum one landing per airport (30) is included, a limit concerning the maximum active flight time (29), maximum four landings per
roundtrip (33) and constraint (31) and (32) preventing the aircraft to arrive and depart from the same depot or airport in the same time period.

$$
\begin{array}{ll}
\sum_{t=1}^{20} \sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r} \geq 1 & j \in A \\
\sum_{t=48}^{T} \sum_{(i, j) \in A R C} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r} \geq 1 & j \in A \tag{35}
\end{array}
$$

| Test 5 | Departure |  | Arrival |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Airpo | Time | Airport | Time |

|  | SSJ | 67 | MJF | 68 |
|  | MJF | 69 | TRD | 74 |

Table 17: Routes from test 5.

The first of the new constraints are constraint number (34), which ensures that at each airport, at least one aircraft have to leave the airport before 10:00 (time period 20). The next constraint is number (35), which says that at least one aircraft have to land at each airport after 17:00 (timer period 48).

Table 17 presents the routes from test 5 . The results shows that all the airports have been visited at least one time in the morning and one time in the afternoon. This time, aircraft 1,2,3 and 4 are used, aircraft 1,2 and 3 also have two roundtrips each. Figure 5 and 6 shows how the aircraft are flying. Figure 5 shows the routes between time period 1 and 38 , and figure 6 shows the route between time period 39 and 76.

Figure 5: The routes between time period 1-38 test 5

Figure 6: The routes between time period 39-76 test 5

### 6.4.6 Conclusion

The model that will be used in the next part of this thesis includes the basic model and all the extensions tested in this chapter. The problem includes in total 28 airports, this makes it too big to run as one, which is why the two-phase solution approach is going to be used. First the Fisher and Jaikumar algorithm will be used to divide into clusters, after that the modified VRP will be used on each of the clusters.

As seen in the tests, the model uses a long computation time when the data file only consists of six airports. This is one of the reasons for dividing into clusters.The result from the testing in NEOS also came back with "no basis", which means that the program cannot be 100 percent sure that the solution found is actually the optimal one, even though it most likely is. This is because the program has not explored all the possible options yet.
We tested the model using time limits of 3 and 7 hours. We could not use more time than that since NEOS automatically terminates the job after 8 hours. The results from the same model tested in 3 and 7 hours, was exactly the same. That is why we have decided to use a time limit of 3 hours when running the model in the next part of the thesis. If there is no solution after 3 hours, we will extend the time limit.

During these tests, we also discovered that constraint (24) is not necessary to include. This is because we have constraint (25) saying that no aircraft can fly in the last periods. Therefore, it will not be included in the model.

In order to display total flight time used in one cluster, the total cost and the distance per aircraft per route, we have included three new sets of variables, a new parameter and three constraints. Variable $D_{p r}$ is the distance flied by aircraft $p$ in roundtrip $r$, variable $T C$ is the total cost of all the routes flied during the time horizon and variable $F T$ is the total flight time for all the legs flied during the time horizon. The parameter $c_{i j}$ is the cost of flying from node $i$ to node $j$. Constraint (36) calculates the distance flied by each aircraft on each roundtrip. The total flight time for all the legs flied in hours are calculated by constraint (37), and the total cost for all the routes are calculated by constraint (38). The variables domains are displayed in (39).

## Decision variables:

| $D_{p r}$ | The distance flied by aircraft $p$ on roundtrip $r$ |
| :--- | :--- |
| $T C$ | The total cost of all the routes flied during the time horizon |
| $F T$ | Total flight time for all the legs flied during the time horizon. |
| Parameters: |  |
| $c_{i j}$ | The cost of flying from node $i$ to node $j$ |

Table 18: Notation - variable and parameters

$$
\begin{equation*}
\sum_{t=1}^{T} \sum_{(i, j) \in A R C} X_{i j p t r} \cdot d_{i j}=D_{p r} \quad p \in P, r \in 1 . . R \tag{36}
\end{equation*}
$$

$\sum_{(i, j) \in A R C} \sum_{t=1}^{T} \sum_{p \in P} \sum_{r=1}^{R} X_{i j p t r} * \frac{t t_{i j} * 15}{60}=F T$
$\sum_{(i, j) \in A R C} \sum_{t=1}^{T} \sum_{p=P} \sum_{r=1}^{R} X_{i j p t r} * C_{i j}=T C$

$$
\begin{equation*}
T C, D_{p r}, F T_{p r} \geq 0 \tag{39}
\end{equation*}
$$

### 7.0 Results

In this section, the results obtained by using the modified VRP on the different clusters found in section 6.3 will be presented. The model and the extensions used are also displayed in appendix H. The different routes, total distance, the total travel time (in hours) and the total cost for the different scenarios will also be presented. In addition, the routes for scenario 3 will be presented in detail. The routes for the rest of the scenarios can be found in appendix $G$.

The data used for solving the scenarios are the same as presented in chapter 4. In addition, we have decided that the maximum number of landings for each aircraft per roundtrip should be equal to five, including the landing at the depot. The maximum number of landings at each airport is two for each aircraft per roundtrip. The aircraft should not go back and forth between airports multiple times, which is the reason why we have restricted the number of visits. These numbers are fixed for all the scenarios, unless something else is stated in the text.

|  | Total <br> distance | Total <br> cost | Total <br> time |
| :--- | ---: | :---: | ---: |
| Scenario 1 | 14061 | 250407 | 50 |
| Scenario 2 | 13646 | 253478 | 49,5 |
| Scenario 3 | 9602 | 212172 | 38,5 |
| Scenario 4 | 9022 | 175137 | 33,75 |
| Scenario 5 | 10194 | 221662 | 44,5 |
| Scenario 6 | 9602 | 213123 | 37,5 |

Table 19: Total distance, cost and time for each scenario

Table 19 shows the total cost, distance and time for each of the scenarios. Scenario 4 is the best solution. This scenario has the shortest distance, uses least time and cost the least. This is because the cost and the time are related to the distance travelled. The seed nodes in scenario 4 are Trondheim, Brønnøysund, Tromsø and Lakselv. The seed nodes are chosen based only on the distance, the total distance travelled are 9022 kilometers. The seed nodes in scenario 5 were chosen based on the location, but the total distance travelled here was 1172 kilometers longer than scenario 4 . Scenario 5 have the following seed

Figure 7: Seed nodes in scenario 5
nodes: Trondheim, Mosjøen, Bodø, Tromsø and Lakselv. These are shown in figure 7, the seed nodes are evenly spread around the country. In theory, scenario 5 should provide a better solution than scenario 4 , since it consists of more seed nodes. This will minimize the distances from the depot to the airports. The reason why scenario 4 gives a better solution in terms of distance, could be because cluster 1 in scenario 4 only consist of Trondheim, which means that there are no aircraft arriving or departing from this seed node. It is not a good solution to have one seed node alone with no airports connected to it.

Scenario 1 and 2 consist only of three seed nodes, which made them harder to solve than the other scenarios. Since there were fewer seed nodes, each cluster became bigger, and the largest cluster consisted of 17 airports including the depot. The challenges we had while trying to solve it are presented in the last part of this chapter.

In the next part the solutions from scenario 3 will be presented.

### 7.1 Scenario 3

This scenario has Trondheim, Bodø, Tromsø and Kirkenes as seed nodes. The reason why this scenario is presented instead of any of the others, is that this scenario is the most likely to be implemented in real life. This scenario is most realistic because each of the seed nodes are located in one of the four regions. The seed nodes chosen are also one of the largest airports in their region.

| Cluster 1 | Cluster 2 | Cluster 3 | Cluster 4 |
| :--- | :--- | :--- | :--- |
| TRD | BOO | TOS | KKN |
| OSY | BNN | NVK | LKN |
| RVK | MJF | EVE | HVG |
|  | SSJ | ANX | MEH |
|  | MQN | BDU | BVG |

|  | SVJ | ALF | VAW |
|  | SKN | HAA | VDS |
|  |  | HFT |  |
|  |  |  |  |

Table 20: Clusters for scenario 3

Table 20 presents an overview over the different clusters in scenario 3, the seed nodes are displayed in bold font. We can see that three out of the four clusters are similar in size. The exception is cluster 1 which only consist of Trondheim, Namsos
and Rørvik. This is because Trondheim is located in the south, and the majority of the airports in our data set are located in the northern part.

Table 21 provides an overview over the total distance travelled in each cluster, the total cost and the total time used in hours. It also presents the number of variable and constraints the model uses. In addition, the solution time is presented in seconds. This is the time used when the solver, which uses a cutting plane approach, finds the best solution. Not the time when it is finished exploring all the possible options.

| Scenario 3 | Distance Cost | Time |  | Best sol. sec | Variables | Constraints |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
| Cluster 1 | 768 | 18256 | 2,5 | 1,14 | 6116 | 4492 |
| Cluster 2 | 3262 | 75866 | 13 | 3822 | 94034 | 53549 |
| Cluster 3 | 3165 | 66977 | 13,75 | 2423 | 90290 | 50795 |
| Cluster 4 | $\mathbf{2 4 0 7}$ | 51073 | 9,25 | 4027 | 97202 | 55675 |
| Total: | $\mathbf{9 6 0 2}$ | $\mathbf{2 1 2 1 7 2}$ | $\mathbf{3 9}$ |  |  |  |

Table 21: Data from all the clusters in scenario 3

Next, each of the clusters in scenario 3 will be presented.

## Cluster 1

Cluster 1 consist of three airports. Those are Trondheim (which is the depot), Namsos and Rørvik. These airports are all located in Trøndelag.

| S3C1 | Departure |  | Arrival |  | Distance | 768 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

|  | RVK | 56 | TRD | 51 |  |  |

Table 22: Results from Scenario 3 Cluster 1

The results from this cluster are presented in table 22. The output shows that the model chooses to use two aircraft, one aircraft in the morning and one aircraft in the afternoon. Aircraft 1 leaves the depot at 06:00 in the morning, then it flies to Namsos, Rørvik, back to Namsos and ends up back at the depot 07:45. Aircraft 2 starts from the depot at 17:15 then it flies Rørvik, Namsos, back to Rørvik and is back at the depot 19:30.

Figure 8: Routes from Scenario 3 Cluster 1

The aircraft visits both Namsos and Rørvik three times, which is equal to the visit frequency. Realistically would this route not be optimal, since it is not necessary to go from Rørvik to Namsos and then back to Rørvik and the other way around. This is because both airports are relatively small and there is not a very high demand on the flight leg between them. In addition, these two airports are close to each other, and it only takes about two hours to travel between them by car. As mentioned in the beginning of this chapter some of the parameters are fixed, for example the number of landings per airport is two for each aircraft per roundtrip.

For cluster 1 we decided to decreased the maximum number of landings on each airport to be one for each aircraft per roundtrip. This is done to remove the option of traveling from Namsos to Rørvik and back to Namsos. The result from this change is shown in table 23.

| S3C1 | Departure |  | Arrival |  | Distance | 1014 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Table 23: Alternative solution for Scenario 3 Cluster 1

When comparing the two alternative solutions, the second solution seems more realistic. Table 23 shows that the model chooses to use two aircraft, aircraft 1 and aircraft 2. In addition, does aircraft 1 travel two roundtrips.

The routes are as following:

Aircraft 1 leaves from the depot at 9:45, goes to Rørvik then to Namsos and lands back at the depot at 11:15. The same aircraft leaves for trip two at 19:15 goes first to Namsos, then to Rørvik and is back at the depot at 20:45. Aircraft 2 leaves from the depot at 07:30, goes to Namsos, then Rørvik and is back at the depot 09:00.

Figure 9: Alternative routes from Scenario 3 Cluster 1

If we compare the distance, cost and time from the two different solutions, we see that when we limit the number of landings per airport per aircraft on each roundtrip the distance increases by 246 kilometers. This is natural since the aircraft can no longer visit an airport two times during the same roundtrip. Since both the time and the cost is linked to the distance of the aircraft, they increases as well.

## Cluster 2

This cluster consist of eight airports, those are Bodø (which is the depot), Brønnøysund, Mosjøen, Sandnessjøen, Mo i Rana, Leknes, Svolvær and Stokmarknes. The routes are represented in figure 10 , here we can see that the solution is divided into two different groups. One group consist of Lofoten (which is Leknes, Stokmarknes and Svolvær) and the other group is Mo i Rana, Mosjøen, Bønnøysund and Sandnessjøen. There are three routes going to Lofoten and there are three routes visiting the other airports. In figure 10, the pink dashed line represents a route that is travelled in both directions each day. The morning flights from Leknes, Stokmarknes and Svolvær lands in Bodø before 08:30. The morning flight from Sandnessjøen, Brønnøysund, Mosjøen and Mo i Rana lands in Bodø by $08: 00$.

Figure 10: Routes from Scenario 3 Cluster 2

Table 24: Results from Scenario 3 Cluster 2

The latest arrival times at the different airports in the evening are as following: Stokmarknes 18:15, Leknes 18:45, Mosjøen 18:45, Brønnøysund 19:15, Svolvær 19:45, Sandnessjøen 19:45 and Mo i Rana 19:00. This is in line with the time constraint. Table 24 shows the flight times and figure 10 displays the routes.

When analyzing the solution, we see that it could have been better to use maximum one landing on each airport for each aircraft per roundtrip, as we did in cluster 1. This is because the aircraft travels from Sandnessjøen to Mosjøen and back again to Sandnessjøen during one flight. The travel time by car from Sandnessjøen to Mosjøen is only about one hour, so it is not necessary to go back and forth between these two airports.

## Cluster 3

In cluster 3, Tromsø is the seed node, and the cluster consists of nine airports. Those are Narvik, Evenes, Andenes, Bardufoss, Storslett, Alta, Hasvik and Hammerfest. In the solution, the routes are divided into two different groups. The first group consists of Andenes, Evenes, Narvik and Bardufoss. In this group, there are two different routes. One

Table 25: Results from Sceanrio 3 Cluster 3
goes from Tromsø to Evenes then to Narvik and back the same way, which is shown as the blue line in figure 11. It is not necessary to travel back and forth between Evenes and Narvik. It is only a one-hour drive between these two airports. The other route in this group is represented with the pink dashed line in figure 11. This route travels from the depot to Andenes, Evenes, Narvik and then back to the depot. The route is travelled two times each day, both times in the same direction. This is a reasonable route that could be implemented in real life, but either Narvik or Evenes needs to be excluded.

The other group consist of Storslett, Alta, Hammerfest and Hasvik. In this group there are three different routes. One goes from Tromsø to Hammerfest, Hasvik, back to Hammerfest and then to Tromsø. This is not an optimal route since the aircraft travels back and forth between two small airports, Hammerfest and Hasvik. Both the airports have a low demand.The next route is more reasonable since it goes from Tromsø to Storslett, Alta, Hammerfest, Hasvik and back to Tromsø. The last route in this group travels from Tromsø to Storslett, Alta, Hammerfest and then back through Alta and to Tromsø. This route is travelled twice each day, each time in different directions. The red dashed line in figure 11 represents this route.

In this cluster there are 3 aircraft used, those are aircraft 1, 2 and 3. In addition, does aircraft 1 and 3 fly three roundtrips each. The morning flight from all the different airports reaches Tromsø before 09:30, and the evening flight visits each of the airports between 19:45 and 22:15.

The routes are shown in table 25 .

Figure 11: Routes from Scenario 3 Cluster 3

## Cluster 4

This last cluster consists of seven airports plus the depot. The airports are Vardø, Vadsø, Båtsfjord, Berlevåg, Honningsvåg, Mehamn, Lakselv and Kirkenes (which is the seed node). This cluster consist of five different routes, three longer ones and two shorter routes. The routes are shown in figure 12. All the longer routes visit both Honningsvåg and Lakselv before going back to Kirkenes. The morning flight reaches Kirkenes before 8:15 from each of the airports. The last flight in the evening lands at Båtsfjord 17:15, Berlevåg 17:45, Mehamn 18:15, Honningsvåg 19:00, Lakselv 19:30, Vardø 21:45 and Vadsø at 22:15.

Table 26: Results from Scenario 3 Cluster 4

Figure 12: Routes from Scenario 3 Cluster 4

In this cluster, most of the routes are reasonable. There is only one route that should have been changed, this route is from Kirkenes, to Vadsø, Vardø, back to Vadsø and then back to Kirkenes. It would have been better if this route was Kirkenes, Vads $\varnothing$, Vardø and then back to Kirkenes.

### 7.2 Conclusion

The overall conclusion is that scenario 3 seems to be the best solution. The routes are realistic, but there are also small changes that we could have done to make the model better. One of those changes would be that for each airport the maximum number of landings should be one for each aircraft per roundtrip. Then we would not have to travel the small distances between for example Rørvik and Namsos more than one time on each flight. Another alternative could be to regulate the number of landings regarding the size of the airport. Lets say that on all medium sized and larger airports the aircraft can land maximum two times on each roundtrip, and on the smaller airports this could be limited to one. This would reduce the number of unnecessary travelling back and forth between small airports with low demands, and at the same time, it would allow the larger airports with high demand to be visited multiple times.

We chose to use visit frequency on each airport instead of the demand. We used this approach because it was not possible for us find the demand on legs not travelled today. When deciding the visit frequency we did not consider the size of the clusters, the size of the airports or which airport the aircraft was arriving from or which airport is was going to visiting next. This makes the visit frequency less realistic. An airport might have a higher visit frequency when it is included in a large cluster, than it would if it was included in a smaller cluster. This is because the airport would then have more options to travel in terms of arcs. A better way would probably be to look at the demand on each arc instead of using visit frequency. We did not use this approach because of the difficulties to collect the necessary data, regarding the demand on each arc. The visit frequency works for our purpose, and it still provides a reasonable solution.

In this thesis, we have only mentioned the PSO regulations to show that there are many factors that need to be considered when deciding the routes. To make the model more realistic, the PSO regulations should been considered more. To do that we could have implemented fixed variables, saying that the leg between two specific airports should be travelled. One example of a PSO regulated route is between Lakselv and Tromsø, this leg should be travelled at least three times daily, and two of them should be non-stop.

### 7.3 Challenges

Some of the clusters consisted of many airports, this lead to challenges when solving the model. Scenario 1 cluster 3 was challenging to solve, because it consists of 16 airports not including the depot. When trying to solve this problem we ended up with 1099742 variables and 576400 constraints. Because of the size of this problem, NEOS ran out of memory before it could find a feasible solution. In order to get a solution for this cluster it was necessary to limit the dataset. This can be done in different ways; one option is to try to limit the model by remove one of the indexes. Another option is to divide the airports into two new clusters, when still keeping the same depot (by either county or north and south of the depot). The third option is to decide some of the flight legs that have to be traversed or some that is not allowed to be flied.

The first option we tried was to remove the roundtrips and instead increase the number of available aircraft. This reduced the problem to 544832 variables and 286865 constraints, but it was still too large to be solved by NEOS. We also tried to limit the problem by fixing some variables, which removed the option of travelling on specific legs. This did not reduce the problem enough to make the model solvable for NEOS.

In order to get a solution for this cluster, we decided to split the cluster into two groups. Both groups would be connected to the same depot. In addition, we made sure that aircraft was not departing or arriving at the depot in the same time period. We split cluster 3 into two equal groups, each consisting of eight airports plus the depot. This reduced the problem to consist of $120386+120878=241264$ variables and $67506+67950=135456$ constraints. Both groups were small enough to be solved by the NEOS solver. To prevent the aircraft from using the depot in the same time period, we solved one of the groups first and analyzed the output to see which time periods the depot was used. Then, when solving the next group, we used fixed variables saying that it was not allowed to arrive or depart from the depot in the same time periods as they did in the first group.

We got the same problem with Scenario 2 Cluster 1. This cluster consists of 10 airports plus the depot. To get a solution we divided the airports into two groups, based on their position to the depot. Group 1 consists of airports south of the depot, and group 2 of airports north of the depot. This way of dividing into two groups could not be done for

Scenario 1 Cluster 3, as the cluster north of the depot would still be too large to get a solution.

### 8.0 Conclusion

The main purpose of this thesis was to make a model for routing of aircraft, with focus on the northern Norway. The northern Norway is a special area because many of the routes there are regulated by the PSO. The area consists of many small airports. In addition, many of the flights are chained air trips with multiple landings on a roundtrip.

The task was to make a relatively easy model using an exact method. We used the basic VRP model as a starting point, and modified this to fit our problem. When modifying the VRP model, we decided to use two routing variables indexed by the arc, aircraft, time and roundtrip. In addition did we extend the model by including time-constraints, constraints regarding roundtrips and constraints regarding time of landing and departure as well as the number of landings. To test the model and see if there was any constraints missing we tested the model on a small instance with six airports. We found that when we added the constraint restricting the aircraft from flying in the last periods, then the computation time increased a lot.

Due to the size of the problem, which consists of in total 28 airports, it became necessary to us a two phase approach to the problem. That is why we implemented a cluster first, route second approach. We used Fisher and Jaikumar to divide the 28 airports into different clusters, and then we used the model we built on these different clusters. Originally, we wanted to try different objective like minimizing total distance, total cost and total travel time to solve the problem. This would not be necessary to do, since the cost and the travel time, is dependent on the distance travelled and the answer would most likely be the same.

We divided the airports into clusters, because the problem was too complex to solve as one. This is not an optimal solution method when considering air traffic. This is because it is harder to see the whole picture, there can be legs that should be traversed between airports in different clusters. To get a realistic solution the whole problem should be solved by using a model for the multi depot VRP.

Our goal was to make a model that gave us feasible solutions that could be implemented in real life. The routes made in some of the scenarios are realistic when comparing it to the routes that are travelled today. There are still a lot more to consider when conducting flight routes. In our model, we only used the PSO regulations as a guide on what to implement regarding time of the flights. If the model is going to conduct routes that could be used in real life all the PSO regulations needs to be taken into consideration.

Further research could be to extend the model regarding more regulations, and implement passenger demand on the legs instead of visits frequency. In order to further develop the model uncertainty could also be implemented.

## Appendix B: Travel times between airports

The table below shows the calculation used to find the travel times between each airport.
The travel times are based on the distance between the airports.

| From: | To: | Time (min): | Distance (km): | km/min: |
| :---: | :---: | :---: | :---: | :---: |
| Bodø | Trondheim | 60 | 467 | 7,8 |
| Kirkenes | Tromsø | 74 | 428 | 5,8 |
| Vadsø | Tromsø | 72 | 416 | 5,8 |
|  |  |  | Average | 6,4 |
|  |  |  | Median | 5,8 |
|  |  |  | Standardeviation | 1,2 |
| Moi Rana | Trondheim | 63 | 367 | 5,8 |
| Tromsø | Bodø | 50 | 323 | 6,5 |
| Sandnessjøen | Trondheim | 50 | 307 | 6,1 |
| Honningsvåg | Tromsø | 75 | 302 | 4,0 |
| Mosjøen | Trondheim | 50 | 299 | 6,0 |
| Kirkenes | Alta | 47 | 261 | 5,6 |
|  |  |  | Average | 5,7 |
|  |  |  | Median | 5,9 |
|  |  |  | Standardeviation | 0,7 |

## Appendix H: The mathematical model used and the notations

The whole model used including the extensions, and excluded the unnecessary constraints.

| Sets: |  |
| :---: | :---: |
| $\begin{array}{r} \mathcal{N} \\ \mathcal{A} \\ \mathcal{P} \\ \text { ARC } \\ \hline \end{array}$ | set of nodes set of airports set of aircraft set of arcs $(i, j) \in A R C, i \in \mathcal{N} \backslash\{N\}, j \in \mathcal{N} \backslash\{0\}$ |
| Parameters: |  |
| P <br> $R$ <br> $R T m a x$ <br> $M$ <br> $R \max$ <br> $v f_{j}$ <br> $d_{i j}$ <br> $t t_{i j}$ <br> $s d$ <br> $l$ <br> $l a$ <br> $c_{i j}$ | Number of time periods <br> Number of roundtrips <br> The longest travel time between the nodes <br> Big number <br> Maximum duration of the route in time periods <br> Visit frequency for node $j \quad j \in \mathcal{A}$ <br> Distance from node $i$ to node $j$ $i \in \mathcal{N}, j \in \mathcal{N}$ <br> Travel time from node $i$ to node $j$ $i \in \mathcal{N}, j \in \mathcal{N}$ <br> Service time at the depot in time periods <br> The maximum allowed number of landings during one roundtrip <br> The maximum allowed number of landings at each airport for each aircraft on each roundtrip <br> The cost of flying from node $i$ to node $j$ <br> $i \in \mathcal{N}, j \in \mathcal{N}$ |
| Decision variables: |  |
| $X_{i j p t r}$ | 1 if aircraft $p$ leaves airport $i$ in time period $t$ to go to airport $j$ on roundtrip $r, 0$ otherwise $(i, j) \in A R C, p \in \mathcal{P}, r \in 1 . . R, t \in 1 . . T$ |
| $Y_{i j p t r}$ | 1 if aircraft $p$ arrives at airport $j$ in time period $t$ from airport $i$ on roundtrip $r, 0$ otherwise $(i, j) \in A R C, p \in \mathcal{P}, r \in 1 . . R, t \in 1 . . T$ |
| $D_{p r}$ | The distance flied by aircraft $p$ on roundtrip $r$ |
| TC | The total cost of all the routes flied during the time horizon |
|  |  |

## Mathematical model

$\min \sum_{(i, j) \in A R C} \sum_{p \in \mathcal{P}} \sum_{t=1}^{T} \sum_{r=1}^{R} X_{i j p t r} * d_{i j}$
